A field experiment was conducted during 2018 at the Instructional Farm, Bidhan Chandra Krishi Viswavidyalaya, Jaguli, Nadia to study the effects of three irrigation regimes (CPE 60 mm, CPE 50 mm and CPE 40 mm) and five nutrition (control, FYM @ 2.5 t/ha, cowdung @ 10 t/ha, poultry manure @ 2.0 t/ha and RDF) on summer cowpea. The results showed that under plenty water supply condition, scheduling of irrigation at CPE 40 accompanied with 100% recommended dose of fertilizers (12.5:25:12.5 kg/ha of N, P and K, respectively) as basal was found to be the best treatment combination for obtaining maximum growth, yield components, pod and seed yield and moderate crop water use efficiency. Under limited or water constraint, deficit irrigation schedule at CPE 50 or CPE 60 in association with 100% RDF was the alternative option for achieving relatively higher pod and seed yield and higher to maximum crop water use efficiency. The seasonal yield response factor for cowpea was found to be 4.64.

### Introduction

Cowpea (*Vigna aunguiculata* L. Walp) is one of the most important food legume and nutritional security crops broadly cultivated in semi-arid regions of the world. It is also a versatile crop well adapted to a diverse soil and climatic conditions of the humid tropics and sub tropical zones. It is primarily cultivated as a *kharif* and summer season vegetable pulse crop in India. Being short duration, it is best accommodated in the

Indian farming system as a main pulse crop, catch crop, cover crop, fodder crop, green manure crop and intercrop under dry land farming as well as irrigated condition. Cowpea is known for its nutritional value for human diet as well as for livestock feed and a source of income generation for resource poor farmers (Sheahan, 2012)<sup>(15)</sup>. It is a major source of carbohydrates (63%) and protein (25%) with low fat content (1.5%) and rich in vitamin A and C, iron, phosphorus, calcium and amino acids like tryptophan and lysine

(Arul Prakasham *et al.*, 2019)<sup>(4)</sup>. The crop has the excellent ability to fix atmospheric nitrogen by root nodules to improve the soil fertility, check soil erosion by deep tap root system and add high amount of organic matter likely to be beneficial for the succeeding crop as well as soil health sustenance (Namakkaet *al.*, 2017)<sup>(11)</sup>. In Indian states, it is mostly produced as a minor pulse crop in arid and semi-arid tracts of Rajasthan, Karnataka, Kerala, Tamil Nadu, Maharashtra and Gujarat and in some pockets areas of Punjab, Haryana, Delhi, West Uttar Pradesh and Rajasthan.

The crop is mainly grown in summer season under rainfed condition. But due to climatic aberrations there was erratic and uneven distribution of rainfall and the crop suffered several stages of soil moisture stress resulting in low productivity or even crop failure. The other reasons for the poor yield are inhabitation of the crop on marginal and sub-marginal land, inadequate or low fertilizer application and no irrigation at critical growth stages during hot summer months. Among the various factors of production, adequate soil moisture availability can lead to greater yield. The crop is susceptible to water stress especially at flowering and pod filling stages and markedly inhibits root hair, nodule growth and biological nitrogen fixation (Onuh and Donald, 2009; Aboamera, 2010)<sup>(13,2)</sup>. Water stress affects the whole process of growth of all organs, metabolism and photosynthesis rate of plant resulting into low production (Zimmermann *et al.*, 1988)<sup>(20)</sup>. Climatological approach based on the cumulative pan evaporation (CPE) is widely practiced as a method of irrigation scheduling as this concept accommodates the entire weather parameters in given soil-water-plant continuum and has higher degree of adaptability at the farmers' level. The crop is responsive to the application of organic and chemical nutrients (Singh *et al.*, 2011a; Daramy *et al.*, 2016; Chemutai *et al.*, 2018)<sup>(17)</sup>.

7. <sup>6)</sup>. Judicious nutrition management under water stress condition can help the plant enduring various stresses (Abedi *et al.*, 2011)<sup>(1)</sup>. The locally available low-cost organic manures like farmyard manure, cattle manure and poultry manure can increase the yield and improve the soil physical conditions in addition to supplying the plant nutrients (Smaling *et al.*, 1993)<sup>(18)</sup>.

In the lower Indo-Gangetic plains, cowpea is a promising and remunerative crop grown successfully during pre-kharif or summer season in upland and medium land. However, the higher productivity of this crop is limited mainly by the inappropriate irrigation and nutrient management practices. The conventional surface flooding method of irrigation commonly followed by the farmers in this region is expensive and inefficient since it causes high water and nutrients losses in deep percolation. Keeping this in view, the present study was contemplated with the objective of examining the effect of irrigation scheduling on growth, yield and yield variables and water use efficiency of cowpea.

## **Materials and Methods**

The field experiment was conducted in summer season on cowpea during 2018 at the Instructional Farm, Bidhan Chandra Krishi Viswavidyalaya, Jaguli, Nadia encompassing the New Alluvial Zone under lower indo-Gangetic plains region of West Bengal. The site is geographically located at 22.93<sup>0</sup>N latitude and 88.53<sup>0</sup>E longitude with an average altitude of 9.75 m above MSL. The experimental soil is sandy clay loam in texture and medium in soil fertility with good drainage and water transmission characteristics. The physical, hydro-physical and chemical properties of the soil are furnished in Tables 1 and 2. The climatological parameters during the cropping period are illustrated in Figure 1. The treatments consisted of three irrigation

regimes (CPE 60 mm, CPE 50 mm and CPE 40 mm) allotted in main plots and five nutrient management (control, FYM @ 2.5 t/ha, cowdung @ 10 t/ha, poultry manure @ 2.0 t/ha and RDF) in sub-plots were laid out in a split-plot design with three replications. Each treatment combination was assigned randomly to the experimental units within a block. The net plot size for each experimental unit was 3 m × 3 m. The entire recommended dose of fertilizers (12.5:25:12.5 kg/ha of N, P and K through urea, single superphosphate and muriate of potash, respectively) was applied uniformly as basal to the whole plot in the holes dibbled earlier at a spacing of 30 cm × 20 cm. The fertilizers were mixed thoroughly and placed at 3-4 cm below the seed to avoid the direct contact of seed with fertilizers. The calculated amount of organic manure was incorporated in the holes of the selected treatments and mixed meticulously with the soil. After manuring and fertilization, two to three cowpea (cv. Rohan 1086) seeds were sown on 20.03.2018 in the holes dibbled at about 5 cm depth and covered with the soil to protect the germinating seeds from bird damage. Thinning was done two weeks later to maintain one plant per hole. The standard agronomic and plant protection measures were followed uniformly. Five plants from the centre of each plot were randomly selected for recording the growth and yield parameters at maturity. Cowpea was harvested manually in several pickings when the pods were fully matured. The green pods from each plot was recorded and exposed to sun drying for 8-10 days, then threshed, cleaned, sun-dried till constant weight obtained and finally the plot wise seed yield was recorded within the period 18.5.2018 to 06.06.2018.

Climatological based different irrigation scheduling was imposed in furrow in the selected plots. Daily evaporation data were recorded from a standard US Weather Bureau Class A Pan installed inside the experimental

site. About 1, 2 and 3 number of irrigation at 50 mm depth each was adopted in irrigation scheduling of cumulative pan evaporation (CPE) at 60, 50 and 40 mm, respectively. Irrigations were applied when CPE reached the desired level and the quantity of water applied was measured with the help of Parshall flume.

Seasonal crop water use or actual crop evapotranspiration (ETa) during the growing period (sowing to harvest) from the cowpea field was computed using the one-dimensional soil water balance equation (Simsek *et al.*, 2005)<sup>(16)</sup> as,

$$ETa = I + P \pm \Delta SW - Dp + Wg - Rf$$

where, I is the amount of irrigation water applied (mm), P is the precipitation (mm),  $\pm\Delta SW$  is the change in soil water storage in the 0-45 cm depth soil profile between sowing and harvest (mm), Dp is the deep percolation (mm), Wg is the amount of water used by crop through capillary rise from groundwater (mm), and Rf is the amount of runoff (mm). The runoff (Rf) and deep percolation (Dp) were assumed to be negligible as the amount of irrigation water applied was managed carefully to prevent over irrigation or runoff.

The capillary rise from groundwater (Wg) was assumed to be negligible as depth of groundwater table was 10-12 m below ground level. The amount of effective rainfall (Re) was calculated by deducting deep percolation (Dp) from precipitation (P). Thus,  $ETa = I + Re \pm \Delta SW$ .

The crop water use efficiency (CWUE) is the seed yield per unit of water used and calculated as,  $CWUE = Y/ETa$  (kg/ha-mm)

Where, Y = dry seed yield (kg/ha) and ETa = actual crop evapotranspiration (mm)

The response of seed yield to water use was quantified through the yield response factor (Ky) and determined by mathematical model (Doorenbos and Kassam, 1980)<sup>(8)</sup>. The growth, yield variables and pod and seed yield data obtained for different treatments were subjected to analysis of variance and statistical significance between means of individual treatments was compared using the least significant difference (LSD) test at  $p < 0.05$  (Gomez and Gomez, 1984)<sup>(10)</sup>.

## Results and Discussion

### Growth and yield components

The growth and yield components of cowpea which considered the indicator of economic yield were significantly influenced by different irrigation regimes and nutrient management for the period (Table 3). The tallest plant (77.38 cm), highest number of nodules per plant (37.08), number of branches per plant (5.77), number of pods per plant (10.61), number of seeds per pod (13.48), maximum pod length (18.17 cm) and 1000-seed weight (67.62 g) were obtained with irrigation schedule at CPE 40 (I<sub>3</sub>) which were superior over irrigation schedule at CPE 50 (I<sub>2</sub>) and CPE 60 (I<sub>1</sub>) except pod length and 1000-seed weight where I<sub>3</sub> and I<sub>2</sub> were statistically on par with each other. Higher deficit irrigation schedule at CPE 60 (I<sub>1</sub>), on the other hand, displayed significantly the shortest plant height (72.27 cm), lowest number of nodules per plant (32.87), number of branches per plant (3.54), number of pods per plant (6.42), number of seeds per pod (10.90), minimum pod length (16.98 cm) and 1000-seed weight (63.02 g). The results revealed that higher soil water availability as a result of higher level of irrigation (I<sub>3</sub>) on regular basis increased the growth and yield contributing parameters, while imposition of moderate (I<sub>2</sub>) or higher deficit irrigation (I<sub>1</sub>) had significantly negative or adverse effects

on plant growth and yield variables due to soil water stress. Adequate soil water availability might have enhanced the water and nutrients absorption as a result of increasing root growth and proliferation due to greater root zone aeration, increasing microbial activities and many biochemical and enzymatic reactions in soil, more production of photosynthates and its translocation in different plant parts which eventually hastened the growth and yield attributes and nodulation of crop. The beneficial effect of irrigation application at two critical stages i.e., at branching stage and pod development stage of crop on the improvement of growth and yield attributes was reported earlier by Game *et al.*, (2014)<sup>(9)</sup> and Rajemahadiket *et al.*, (2018)<sup>(14)</sup>.

As regards to nutrient management, the addition of 100% RDF (F<sub>4</sub>) recorded the maximum plant height (85.25 cm), number of nodules per plant (41.95), number of branches per plant (5.74), number of pods per plant (10.60), number of seeds per pod (13.95), pod length (18.37 cm) and 1000-seed weight (69.79 g) which were significantly superior to the remaining organic nutrient treatments. The next higher growth and yield variables were recorded with cowdung manure (F<sub>2</sub>), poultry manure (F<sub>3</sub>) and FYM (F<sub>1</sub>) in descending order, respectively. The least growth and plant variables were obtained with the treatment receiving no chemical fertilizers and organic manures. The findings amply suggest that application of inorganic NPK fertilizers might have guaranteed the optimum availability of nutrients in soil which in turn encouraged the plant to be more photosynthetically active for increasing vegetative growth and yield contributing characters. On the other hand, application of various organic substrates having slow nutrients releasing characteristics was not sufficient enough to meet the plant nutrition at all growth stages resulting in moderate

growth and yield contributing parameters. The obtained results are in agreement with the findings of Game *et al.*, (2014)<sup>(9)</sup>.

The interaction effects between irrigation and nutrient management showed that tallest plant height (88.11 cm) and maximum number of nodules per plant (44.36), number of branches per plant (7.39), number of pods per plant (12.41), number of seeds per pod (15.09), pod length (19.14 cm) and 1000-seed weight (72.27 g) were found with irrigation schedule at CPE 40 coupling with 100% RDF (I<sub>3</sub>F<sub>4</sub>) which were superior to the remaining treatment combinations excepting the number of seeds per pod and pod length where the interaction effects were non-significant. This was ascribed to the higher availability and absorption of water and nutrients by plant throughout the growth stages as a result of recommended dose of fertilizers application under the optimum irrigation regime. Low nutrients supply from organic inputs under soil moisture stress as a consequence of deficit level of irrigation application might have resulted declined growth and plant parameters. The lowest growth and plant attributes were recorded with deficit irrigation at CPE 60 without manuring and fertilization (I<sub>1</sub>F<sub>0</sub>).

### **Green pod and seed yield**

Application of differential irrigation regimes and inorganic and organic nutrients had significant variations on green pod yield and seed yield of cowpea (Table 3). Among the variable irrigation levels, highest green pod yield (41.36 q/ha) and seed yield (11.36 q/ha) was recorded from irrigation at CPE 40 which was statistically superior to moderate deficit irrigation at CPE 50 and higher deficit irrigation at CPE 60 with the corresponding values of 40.50 q/ha and 10.74 q/ha and 39.11 q/ha and 10.24 q/ha, respectively. It is conspicuous that deficit irrigation regimes

might have failed to mitigate the plant water requirement possibly due to high soil water stress which restricts transpiration, stomatal opening and reduced <sup>14</sup>CO<sub>2</sub> fixation resulting in low photosynthetic activity and retarded growth and expansion of leaf area and eventually depressed the pod and seed yield (Nemeskéri and Helyes, 2019)<sup>(12)</sup>. This amply indicates that maintenance of no soil water stress with optimum irrigation supply all through the growth stages is imperative in increasing the yield, probably due to better water and nutrient distribution and utilization by plant and excellent soil-water-air relationship with higher oxygen concentration in the root zone (Acar *et al.*, 2008)<sup>(3)</sup>.

Similarly, application of 100% RDF (F<sub>4</sub>) displayed maximum green pod yield (44.20 q/ha) and seed yield (12.83 q/ha) which were significantly superior over the remaining organic nutrient treatments. Subsequent higher yields were found with cowdung manure (F<sub>2</sub>), poultry manure (F<sub>3</sub>) and FYM (F<sub>1</sub>) in decreasing order, respectively. The lowest yields were obtained with the control treatment receiving no inorganic and organic fertilizers. The results indicate that ready supply of macronutrients through recommended chemical fertilizers might have assured optimum nutrients availability in soil which in effect promoted carbohydrate synthesis by photosynthesis, increases assimilate production and ultimately allocation to seed that increased the size and weight of pod and enhanced seed yield (Tsegaye *et al.*, 2016)<sup>(19)</sup>. Contrary to this, the different organic components having slow nutrients releasing characteristics were not adequate sufficient to satisfy the plant nutrition demand at all growth stages resulting in moderate yields. These results are in harmony with the findings of Rajemahadik *et al.*, (2018)<sup>(14)</sup> that 100% RDF below seed placement recorded significantly the higher grain yield.

The interaction effect between irrigation regimes and nutrient management on pod and seed yield was not statistically significant (Table 3). However, maximum pod yield (45.61 q/ha) and seed yield (13.62 q/ha) was registered with the treatment combination of irrigation schedule at CPE 40 with 100% RDF (I<sub>3</sub>F<sub>4</sub>) which was followed immediately by irrigation at CPE 50 with 100% RDF (I<sub>3</sub>F<sub>2</sub>) and irrigation at CPE 40 with cowdung manure (I<sub>3</sub>F<sub>2</sub>) with the corresponding values of 44.41 and 12.63 q/ha and 43.31 and 12.79 q/ha, respectively. However, under water constraint, deficit irrigation schedule at CPE 60 in association with 100% RDF (I<sub>1</sub>F<sub>4</sub>) was the alternative option recording relatively moderate pod and seed yield. Minimum pod yield (35.12 q/ha) and seed yield (7.50 q/ha) was recorded with deficit irrigation at CPE 60 without nutrient addition (I<sub>1</sub>F<sub>0</sub>). Higher water availability under favourable irrigation regime complemented with readily available chemical fertilizers might have facilitated better water and nutrient use by plant resulting in higher yield. Conversely, deficit

irrigation regime without addition of nutrients rendered a harmful effect on yield reduction. The results corroborated with the observations of Game *et al.*, (2014) <sup>(9)</sup> who reported the non-significant relationship between irrigation and fertilizer on pod yield in cowpea.

### Seasonal crop water use and crop water use efficiency

The different components of soil water balance during the cropping period under different irrigation regimes and nutrition are presented in Table 4. The depth of water applied under irrigation scheduling at CPE 60 mm (I<sub>1</sub>), CPE 50 mm (I<sub>2</sub>) and CPE 40 mm (I<sub>3</sub>) was 50, 100 and 150 mm, respectively.

The effective rainfall during the experimental period was 38.5 mm, whereas the soil profile contribution ranged from 20.8 to 25.4 mm. Thus the seasonal crop water use or, actual crop evapotranspiration (ETa) under irrigation scheduling of I<sub>1</sub>, I<sub>2</sub> and I<sub>3</sub> was 112.0, 161.4 and 210.6 mm, respectively.

**Table.5** Relationship between the decrease in relative water use and decrease in relative yield for cowpea

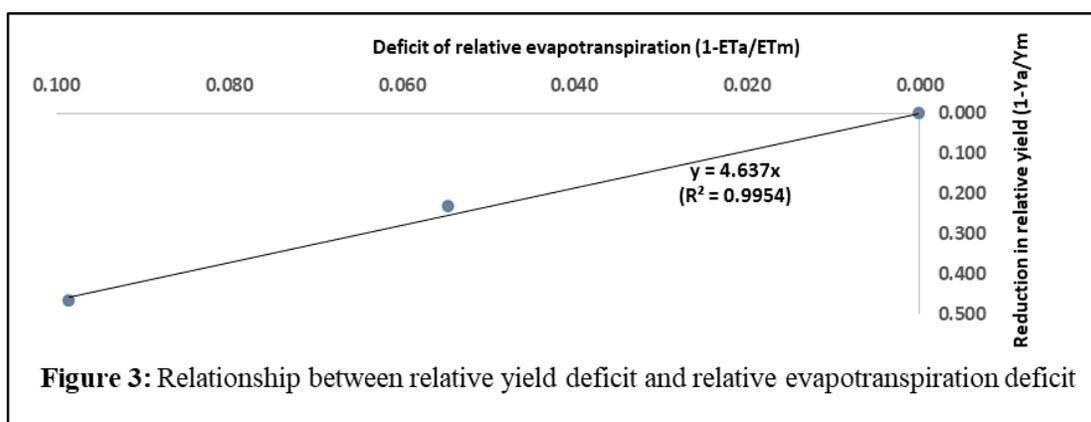

Irrigation schedule	ETa (mm)	ETm (mm)	(1-ETa/ETm)	Ya (kg/ha)	Ym (kg/ha)	(1-Ya/Ym)	Ky
CPE 40	210.60	210.60	0.000	1136	1136	0.000	0
CPE 50	161.42	210.60	0.234	1074	1136	0.055	0.234
CPE 60	112.04	210.60	0.468	1024	1136	0.099	0.211

I<sub>1</sub>: CPE 60 mm, I<sub>2</sub>: CPE 50 mm, I<sub>3</sub>: CPE 40 mm

**Figure 2:** Water-yield relationship for cowpea

**Figure 3:** Relationship between relative yield deficit and relative evapotranspiration deficit

The results indicate that maximum crop water use efficiency (CWUE) of 10.75 kg/ha-mm was obtained with irrigation scheduling at CPE 60 coupling with RDF (I<sub>1</sub>F<sub>4</sub>) which was followed by irrigation at CPE 60 along with cowdung (I<sub>1</sub>F<sub>2</sub>) as 10.39 kg/ha-mm and CPE 60 with poultry manure (I<sub>1</sub>F<sub>3</sub>) as 9.72 kg/ha-mm. Minimum WUE of 4.09 kg/ha-mm was recorded with irrigation scheduling at CPE 40 without nutrition (I<sub>3</sub>F<sub>0</sub>). This indicates that the crop imposed under higher deficit irrigation schedule at CPE 60 in conjunction with recommended dose of mineral fertilizers or, poultry manure might have used all irrigation water applied for production function resulting in higher crop water use efficiency.

### Crop yield - water production function

The relationship between cowpea seed yield (y) and the quantity of irrigation water applied

(x) was computed by regression analysis. Seed yield was taken as dependent variable and plotted against 'x' to derive a mathematical function (Figure 2). A strong linear relationship was best fitted between y and x as,  $y = 0.0112x + 9.66$  ( $R^2 = 0.996$ )

The graph indicates that the increase in seed yield was proportional to the increase in water application. This model approach can successfully be used for predicting yield under different irrigation water supply. The highest reduction in seed yield was observed with deficit irrigation at CPE 60 (9.9%) followed by CPE 50 (5.5%) as against optimum irrigation at CPE 40 which might have resulted more negative effect on crop through higher soil water deficit. This predictive model can also serve as a good guideline for cowpea growers in the lower Indo-Gangetic plains region to yield potential

allocation decision related to varying water supply condition. The above results are in line with the observations of Bozkurt *et al.*, (2011)<sup>(5)</sup> who found significant linear relationship between crop yield-water production function for hybrid corn in eastern Mediterranean climatic condition, especially in the deficit irrigation range, because all the applied water was used by crop.

### Crop yield response factor (Ky)

The response of seed yield of cowpea to water use during growing season is quantified through the yield response factor ( $K_y$ ) and was computed using the equation given by Doorenbos and Kassam (1979)<sup>(8)</sup> as

$$K_y = \frac{1 - Y_a/Y_m}{1 - E_{Ta}/E_{Tm}}$$

Where,  $Y_a$  is the actual seed yield (kg/ha),  $Y_m$  is the maximum seed yield (kg/ha),  $E_{Ta}$  is the actual evapotranspiration (mm) and  $E_{Tm}$  is the maximum evapotranspiration (mm) and  $K_y$  is the response factor to deficit irrigation.  $K_y$  is the slope of the linear relationship between the reduction in relative yield and the reduction in relative evapotranspiration. It shows the response of yield with concomitant decrease in water consumption. In other words, it explains the decline in seed yield with respect to per unit decrease in water use. The relationship between relative yield deficit and relative evapotranspiration deficit for cowpea is furnished in Figure 3. The seasonal yield response factor ( $K_y$ ) was found to be 4.64 with high coefficient of determination ( $R^2 = 0.99$ ). The value of  $K_y$  increased first with increase in water deficit and then marginally decreased with further increase in water deficit (Table 5). This reveals the fact that the yield decrease was not proportional to the higher degree of water stress. The higher seasonal  $K_y$  value under water stress

condition indicates that the plant will have a greater yield loss when the optimal crop water requirements are not fulfilled. This also implies a high impact of soil water stress condition on the seed yield. According to the proposition of Doorenbos and Kassam (1979)<sup>(8)</sup> that if  $K_y > 1.0$ , the reduction in yield is proportionally larger with decrease in water use as the crop is very sensitive to soil water deficit. Thus maintenance of optimum soil water regime by proper irrigation scheduling based CPE at all growth stages of cowpea is very imperative.

In conclusion, the under plenty or assured water supply condition, scheduling of irrigation at CPE 40 accompanied with 100% recommended dose of fertilizers (12.5:25:12.5 kg/ha of N, P and K, respectively) as basal was found to be the best treatment combination for obtaining maximum growth, yield components, pod and seed yield and moderate crop water use efficiency of summer cowpea. Under water constraint, deficit irrigation schedule at CPE 60 complemented with 100% RDF was the alternative option furnishing relatively higher pod and seed yield and maximum water use efficiency of the crop grown in the lower Indo-Gangetic plains of West Bengal.
