#### ABSTRACT

Feeding the global population, 7.8 billion in as of November 2020 and projected to increase to 9.5 billion by 2050 and 11.2 billion by 2100, necessitates an increase in agricultural production of ~70% between 2005 and 2050. Soil deterioration, characterized by decline in quality and decrease in ecosystem goods and services, is a major constraint to achieving the required increase in agricultural production. Soil is a non-renewable resource on human time scales with its vulnerability to deterioration depending on complex interactions between processes, factors and causes occurring at a range of spatial and temporal scales. Among the major soil deterioration processes are accelerated erosion, depletion of the soil organic carbon (SOC) pool and loss in biodiversity, loss of soil fertility and elemental imbalance, acidification and salinization. Soil deterioration trends can be reversed by conversion to a restorative land use and adoption of recommended management practices. The strategy is to minimize soil erosion, create positive SOC and N budgets, enhance activity and species diversity of soil biota (micro, meso and macro), and improve structural stability and pore geometry. Improving soil quality (*i.e.*, increasing SOC pool, improving soil structure, enhancing soil fertility) can reduce risks of soil deterioration (physical, chemical, biological and ecological) while improving the environment. Increasing the SOC pool to above the critical level (10 to 15 g/kg) is essential to set-in-motion the restorative trends. Site-specific techniques of restoring soil quality include conservation agriculture, integrated nutrient management, continuous vegetative cover such as residue mulch and cover cropping, and controlled grazing at appropriate stocking rates. The strategy is to produce “more from less” by reducing losses and increasing soil, water, and nutrient use efficiency.

#### Introduction

Of the 5.5 billion people living in developing countries in 2014 (Van Pham and Smith, 2014), a large proportion of them depend on

agriculture for their livelihood. In fact, one billion of these people are small landholders who cultivate <2 ha of land (IFAD, 2011). With limited resources and poor access to

inputs, management of soil quality is essential to strengthen and sustain ecosystem services. Soil deterioration is a 21st century global problem that is especially severe in the tropics and sub-tropics. Some estimates indicate deterioration decreased soil ecosystem services by 60% between 1950 and 2010 (Leon and Osorio, 2014). Accelerated soil deterioration has reportedly affected as much as 500 million hectare (Mha) in the tropics, and globally 33% of earth's land surface is affected by some type of soil deterioration. In addition to negatively impacting agronomic production, soil deterioration can also dampen economic growth, especially in countries where agriculture is the engine for economic development. Over and above the environmental and economic impacts, there are also health risks of soil erosion and other deterioration processes.

Soil deterioration implies a decline in soil quality with an attendant reduction in ecosystem functions and services. Conceptually, there are four types of soil deterioration: (i) physical; (ii) chemical; (iii) biological; and (iv) ecological (Figure 1). Soil physical deterioration generally results in a reduction in structural attributes including pore geometry and continuity, thus aggravating a soil's susceptibility to crusting, compaction, reduced water infiltration, increased surface runoff, wind and water erosion, greater soil temperature fluctuations, and an increased propensity for desertification. Soil chemical deterioration is characterized by acidification, salinization, nutrient depletion, reduced cation exchange capacity (CEC), increased Al or Mn toxicities, Ca or Mg deficiencies, leaching of NO<sub>3</sub>-N or other essential plant nutrients, or contamination by industrial wastes or by-products. Soil biological deterioration reflects depletion of the soil organic carbon (SOC) pool, loss in soil biodiversity, a reduction in

soil C sink capacity, and increased greenhouse gas (GHG) emissions from soil into the atmosphere. One of the most severe consequences of soil biological deterioration is that soil becomes a net source of GHG emissions (*i.e.*, CO<sub>2</sub> and CH<sub>4</sub>) rather than a sink. Ecological deterioration reflects a combination of other three, and leads to disruption in ecosystem functions such as elemental cycling, water infiltration and purification, perturbations of the hydrological cycle, and a decline in net biome productivity. The overall decline in soil quality, both by natural and anthropogenic factors, has strong positive feedbacks leading to a decline in ecosystem services and reduction in nature conservancy. Once the process of soil deterioration is set-in-motion, often by land misuse and soil mismanagement along with the extractive farming, it feeds on itself in an ever-increasing downward spiral (Figure 2).

The objectives of this review are to: (1) deliberate the role of soil resources in provisioning essential ecosystem services; (2) illustrate the impacts of soil deterioration on decline in ecosystem services; and (3) identify strategies for improving soil quality to mitigate risks of soil deterioration.

### **Soil and ecological resources**

Soil, the most basic of all resources, is the essence of all terrestrial life and a cultural heritage. Yet, soil is finite in extent, prone to deterioration by natural and anthropogenic factors, and is non-renewable over the human timescale (decades). Soil quality also has strong implications to human health, thus illustrating its important role in both society and the environment. Because of numerous ecosystem services provisioned through soils (*e.g.*, food, feed, fiber, climate moderation through C cycling, waste disposal, water filtration and purification, elemental cycling)

(Robinson *et al.*, 2012), soil quality must be protected or restored to enhance these services. Increased public awareness and a fundamental understanding of basic pedospheric processes (*i.e.*, biology, chemistry, physics, pedology, ecology) are essential both to enhancing long-term productivity and improving the environment.

### **Effect of SOC on soil quality**

The SOC pool, including its quantity and quality, is the defining constituent of soil. Indeed, SOC pool is the most reliable indicator of monitoring soil deterioration, especially that caused by accelerated erosion. Soil deterioration depletes the SOC pool, along with it, plant available N and other essential nutrients such as P and S. Furthermore, as identified repeatedly in this special issue of Sustainability, depletion of SOC pool is a global issue and a principal cause of soil deterioration, especially in the European semi-arid Mediterranean regions. Developing strategies to ensure the SOC pool is to increase and preferably maintain above the threshold or critical level of 10 to 15 g/kg (1.0%–1.5%), which is essential for reducing soil deterioration risks and reversing deterioration trends. Integrated nutrient management (INM) is one strategy that embodies sustainable management of the SOC pool and its dynamics (Vanlauwe *et al.*, 2012). Adoption of INM or similar management practices that create a positive soil/ecosystem C budget can not only increase productivity but also sequester additional atmospheric CO<sub>2</sub> into the SOC pool. This has been documented for many surface soils within the U.S. Corn Belt which act as C sinks when corn (*Zea mays* L.) is grown using recommended management practices (RMPs) such as conservation agriculture (CA) (Clay *et al.*, 2012). There also exists a strong relationship between vegetation cover and the SOC pool, such that

excessive reductions in vegetation cover exacerbates risks of soil deterioration and SOC depletion. A study conducted in the sub-tropical humid grasslands in South Africa indicated that the decline in grass (vegetative) cover from 100% to 0%–5% reduced the SOC pool by 1.25 kg/m<sup>2</sup> and the soil organic N (SON) pool by 0.074 kg/m<sup>2</sup> (Dlamini *et al.*, 2014). There were also attendant declines in the C:N ratio and proportion of SOC and SON in the silt + clay fraction with the decline in aerial grass cover which negatively affected ecosystem functions of the acidic sandy loam soils. Similarly, transformation of a thicket vegetation to an open savanna (dominated by grasses) due to intensive grazing decreased soil quality in the Eastern Cape region of South Africa. Indeed, savanna soils have lower SOC concentration and a greater tendency to crust than thicket soils because of the decreased quantity and stability of structural aggregates.

The widespread prevalence of degraded soils in sub-Saharan Africa (SSA), a classic example of a downward spiral, is attributed to over exploitation, extractive farming, low external inputs, and poor or improper management (Figure 2). Accelerated deterioration is shrinking the finite soil resource even more rapidly in these regions of harsh climate and fragile soils. In this context, enhancing the SOC pool is important to sustain soil fertility and agronomic productivity. Simply adding chemical fertilizers or improved varieties, as is often erroneously recommended even by well-intended advocates, is not enough.

The SOC pool of agricultural soils of West Africa, similar to those of croplands in other developing countries (e.g., South Asia), is severely depleted by over-exploitation of natural resources. These soils must therefore be managed to increase both soil C and vegetation to restore the degraded

agroecosystem services. Changes in aerial vegetative cover could thus be used as an early indicator of shifts in soil ecosystem functions within fragile environments. A shift in vegetative cover may be caused by alterations in land use or climate change. In addition to SOC and SON pools, soil moisture regime is another important indicator of climate change (Eaton *et al.*, 2012). In conjunction with changes in soil moisture regimes, projected global warming may also influence SOC decomposition rates including that of fine woody debris. Field experiments have shown that warming increases mass loss for all vegetative species and size classes by as much as 30%. However, larger debris and that with higher initial lignin content decomposes more slowly than smaller debris and that with lower antecedent lignin content. Indeed, deterioration of lignin may not follow the same trend as that of total mass loss (Berbeco *et al.*, 2012). Along with the adverse effects of soil erosion and other deterioration processes, the SOC pool is also prone to climate change and associated alterations in temperature and moisture regimes.

The self-reinforcing soil deterioration process (Figure 2) is strongly exacerbated by the interaction between processes, factors and causes of soil deterioration (Figure 3). Processes include the mechanisms (types) of soil deterioration. Factors comprise agents of deterioration related to natural or anthropogenic drivers such as climate, physiography, socio-economic or ethnic/cultural parameters. Causes of soil deterioration include specific activities which aggravate the adverse effects of processes and factors. Examples of specific causes include activities such as deforestation, land use conversion, extractive farming practices or over-exploitation, excessive grazing, excessive plowing *etc.* (Figure 3). The process-factor-cause nexus is strongly

impacted by site-specific conditions. Thus, understanding the nexus or connectivity is critical to restoring soil quality and mitigating deterioration.

### **Role of soil quality indicators in determining soil health**

The SOC pool is a key indicator of soil quality, and an important driver of agricultural sustainability. In addition to its amount, other parameters of SOC include its depth distribution, quality or attributes (physical, chemical, biological), and the turnover rate or the mean residence time (MRT). Relevant indicators of soil physical quality include amount and stability of aggregates; susceptibility to crusting and compaction; porosity comprising of pore geometry and continuity; water transmission (infiltration rate and amount) and retention as plant-available water capacity (PAWC); aeration and gaseous exchange; effective rooting depth; soil heat capacity and the temperature regime. Similarly, appropriate indicators of soil chemical quality include pH, CEC, nutrient availability; and favorable elemental balance and lack of any toxicity or deficiency. Relevant indicators of soil biological quality are microbial biomass C (MBC), activity and diversity of soil fauna and flora, absence of pathogens and pests as indicated by a soil's disease-suppressive attributes. An optimal combination of these properties affects agronomic productivity; use efficiency of water, nutrients and other inputs; and sustainability of management systems. Indicators of soil quality differ among soil types, climates and land uses. For example, there are specific soil quality indicators for the intensively managed soils of the Indo-Gangetic Plains (Ray *et al.*, 2014) that will differ from those for tropical Alfisols in semi-arid regions. A spectral soil quality index based on application of reflectance spectroscopy has also been

proposed as a diagnostic tool to assess soil quality (Paz Kagan *et al.*, 2014). This technique can provide a characterization of physical, chemical and biological attributes that can be merged together to indicate how well a soil is functioning for a specific use.

### **Conservation farming and soil health**

Four basic principles of CA are (Lal, 2015): (i) retention of crop residue mulch; (ii) incorporation of a cover crop in the rotation cycle; (iii) use of INM involving combination of chemical and bio fertilizers; and (iv) elimination of soil mechanical disturbances. Properly implemented on suitable soil types, CA has numerous co-benefits including reduced fuel consumption and increased soil C sequestration. Mechanical tillage is an energy-intensive process (Rodriguez and Hernandez, 2013) and its reduction or elimination can decrease consumption of fossil fuels. For example, conversion from plow tillage (PT) to CA can reduce diesel consumption by as much as 41 L/ha (Labreuche *et al.*, 2011).

In addition, an increase in SOC pool under CA can occur in soils not prone to accelerated erosion, and those which have optimal management strategies. A modeling study in Western Kenya showed that site-specific optimal management strategies can lead to SOC pool of 20 to 40 Mg/ha in 0.1 m depth and corn grain yield of 3.5 to 4.2 Mg/ha. The most desirable tillage systems are those which restore soil quality, minimize risks of soil erosion, improve use efficiency of rain water and fertilizers and minimize risks of SOC and nutrient depletion. Impacts of CA on soil quality restoration, an example of an upward spiral, is outlined in Figure 4.

Indiscriminate use of plowing, coupled with excessive removal of crop residues and unbalanced use of chemical fertilizers, can

degrade soil quality, deplete SOC pool, and aggravate risks of soil erosion (Figure 2). In contrast, conversion of plow/traditional tillage to CA, especially on sloping lands and those vulnerable to accelerated erosion by water and wind under conventional management, can be conservation-effective, reverse deterioration trends, and set-in-motion soil restoration processes with an upward spiral (Figure 4). Retention of crop residue mulch, and incorporation of a cover crop (forages) in the rotation cycle while eliminating bare fallows, can conserve soil and water and improve SOC pool in the surface layer (Figure 4). Increases in soil biodiversity, MBC and activity of earthworms and termites can all improve aggregation and encapsulate C within stable micro-aggregates as outlined in the hierarchy concept. Strengthening elemental cycling, in conjunction with coupled cycling of C and H<sub>2</sub>O, can increase the solum's C sink capacity and soil profile depth through increased bioturbation by earthworms or termites, and use of deep-rooted plants such as pigeon pea (*Cajanus cajan*), townsville stylo (*Stylosanthes humilis* (Kunth) Hester), or alfalfa (*Medicago sativa*). Long-term (>10 years) soil quality improvement will increase net biome productivity, improve water and nutrient use efficiencies, and increase above and below-ground biomass-C within the ecosystem. Progressive improvements in rhizospheric processes, driven by biotic mechanisms, would restore soil quality and mitigate deterioration (Figure 4). It is important to note, however, that CA is a holistic and system-based approach. Mere elimination of plowing, while removing an excessive amount of crop residues and biomass for other uses (e.g., biofuels, industrial purposes) is not CA, and is rather an extractive farming system with negative impacts on soil and the environment. Thus, comparative analyses of un-related datasets can lead to erroneous assessments of SOC

sink capacity associated with a properly implemented CA system (Powlson *et al.*, 2014) and misinterpretation of agronomic yields (Pittelkow *et al.*, 2015). Furthermore, improvements in soil quality require more than the input of new varieties and chemical fertilizers (Sanchez, 2015). The real issue is improving physical, biological and ecological components of soil quality, and set-in-motion an upward spiral eventually leading to social and political stability and international security (Figure 4).

### **Restitution of soil quality by management of soil fertility**

Sustainable intensification (SI), producing more from less by reducing losses and increasing the use efficiency, is attainable only through improvement of soil quality including chemical quality or soil fertility. Although not the only way to increase soil fertility, the use of INM is a very effective approach for achieving SI. Nutrient depletion and loss of soil fertility are major causes of low productivity in many developing countries. Use of organic amendments, by recycling organic by-products including urban waste, is a useful strategy to enhance soil fertility, and improve structural stability or aggregates. While, nitrogen (N) input is important to improving soil fertility, its improper and/or excessive use can also lead to environmental pollution. China consumes about 30% of the world's N fertilizer, and is able to feed ~22% of the world population on just 6.8% of the global cropland area. However, the country has severe environmental problems because of low N use efficiency, leaching of reactive N into surface and groundwater resources, and emission of N (as N<sub>2</sub>O) into the atmosphere.

### **Water resources and soil health**

High soil quality or a healthy soil provides the foundation for a healthy economy,

environment, and terrestrial biosphere. Thus, there exists a close link between soil quality and water resources in close proximity, such as the health of coastal ecosystems. Changes in land use often affect water quality and pollutant loading (Khaledian *et al.*, 2012). Off-site movement of agricultural chemicals is often a significant source of non-point pollution. Many of the major rivers in countries with emerging economies have severe water pollution, contamination and eutrophication problems. Downstream areas are often adversely affected because of adhoc agricultural development activities upstream. Among the most important adverse impacts are river desiccation, ground water depletion, surface and ground water pollution, accelerated erosion, sedimentation, salinization, and nutrient depletion. These problems are especially severe in densely populated regions (e.g., East Asia, South Asia). Rapid urbanization, industrialization and increases in water demand have created severe water quality problems and deterioration of the Ganges. Land use changes induced by urbanization have had strong impacts both on soil and water quality in northern Iran. Release of P from agricultural sources to streams and rivers has become a major factor affecting surface water quality not only in China, but also in the Great Lakes of North America (e.g., algal bloom of 2014). In Thailand, agriculture [especially rice (*Oryza sativa*) farming] is the key nutrient source within the Thachin River Basin. Recent industrialization and community development have exacerbated water pollution and habitat deterioration in the Gulf of Thailand. The problem has been exacerbated by a rapid decrease in mangrove forest, coral reefs, and fishery resources due to misuse and mismanagement.

Irrigated agriculture, an important management strategy for high agronomic productivity in arid and semi-arid regions, is a mixed blessing. Mismanagement of

irrigation waters has exacerbated problems with saline-sodic soils which now occupy more than 20% of the irrigated lands. Furthermore, arid wetlands are also prone to contamination by sub-surface agriculture irrigation and drainage as in the Western USA. These areas often experience toxicity problems in fish and wildlife due to drainage of water contaminants. In response, provisions must be made to reduce the amount of contaminants entering wetlands, and to provide for better allocation of freshwater between agriculture and wildlife. Salinity problems are also often confounded by the reuse of untreated waste water (gray/black water) in agriculture (Dakoure *et al.*, 2013), especially in urban areas prone to water shortages or those having water resources of marginal quality.

Restoring soil quality within managed ecosystems is critical to improving and sustaining water quality. To accomplish this goal, it is essential to develop strategies for integrated management of soil and water resources because of their strong inter-connectivity or the soil-water-waste nexus. While integrated water management alone is useful, the importance of the soil-water nexus cannot be over-emphasized. Management of sediments, especially contaminated ones, is another important component of the soil-water nexus that must be critically examined.

### **Approaches for soil quality restitution**

Restoring the quality of degraded soils is a challenging task, especially in regions dominated by small, resource-poor landholders. Re-carbonization of the depleted SOC pool, which is essential to numerous functions, requires regular input of biomass-C and essential elements (*i.e.*, N, P, and S) (Lal, 2014). Thus, restoration of soil quality is a societal, national and international task that necessitates a coordinated approach.

There are three basic strategies of restoring soil quality (Figure 5): (i) minimizing losses from the pedosphere or soil solum; (ii) creating a positive soil C budget, while enhancing biodiversity; and (iii) strengthening water and elemental cycling. There is no silver bullet or panacea to accomplish these basic tasks, and site-specific factors (biophysical, social, economic, cultural) play a significant role.

### **Soil erosion management**

Soil erosion must be curtailed to within the tolerable limits, which is often much less than the presumed value of 12.5 Mg/ha per year. Accelerated erosion also depletes the SOC pool and nutrient reserves. In general, the enrichment ratio of SOC, clay and essential plant nutrients (N, P, S) is  $>1$  (and most often as much as 5 or more) because of the preferential removal of these constituents. Conversion from PT to CA can reduce risks associated with soil erosion and nutrient loss while also providing numerous on- and off-site benefits (Figure 4). An important strategy is to establish cause-effect relationships, alleviate the causative factors and minimize the risks. Accelerated erosion is a symptom of land misuse and soil mismanagement. Reductions in plant cover caused by overgrazing and the trampling effect can degrade soil structure, reduce water infiltration, increase runoff, aggravate soil erosion, and cause severe economic losses. As an example, experiments conducted in South Africa indicated that plant cover reduction by overgrazing significantly decreased the SOC pool with strong impact on the C cycle (Mchunu and Chaplot, 2012). In arid regions, fire-induced depletions of the vegetation cover can also exacerbate the problem, especially after a torrential rainfall because ash left on the soil surface can aggravate hydrophobicity by creating an obtuse contact angle between the solid and liquid phases.

When the protective litter cover is burned, the very first rainfall generally results in high surface runoff and aggravates erosion as was the classic situation of wild fire in May–June 2000 in hills which threatened the Los Alamos National Laboratory by runoff and sedimentation. Experiments conducted in Spain indicated high post-fire soil deterioration risks and the need for identification of a short-term strategy to conserve soil and water on steep slopes with erodible soils. In addition to the adverse effects on soil quality and productivity, there are also health risks associated with soil erosion. This is especially true for regions prone to wind erosion and dust storms, such as the Harmattan in the Sahel.

### **Refinement of soil/agro-biodiversity**

Soil biota are important to soil quality and reduce risks of deterioration and desertification. Indeed, soil biota comprise a major component of global terrestrial biodiversity and perform critical roles in key ecosystem functions (e.g., biomass decomposition, nutrient cycling, moderating CO<sub>2</sub> in the atmosphere, creating disease suppressive soils, *etc.*). Improving activity and species diversity of soil fauna and flora (micro, meso and macro) is therefore essential to restoring and improving soil quality and reducing risks of soil deterioration. Adverse effects of agricultural management on soil microbiological quality is another global concern. As a management tool, either a microbiological quality index or a microbiological deterioration index can be useful for decision-making processes. Relevant parameters include MBC, respiration, water soluble carbohydrates, enzymatic activities, dehydrogenase activity and activities of other important hydrolases (e.g., urease, protease, phosphatase and  $\beta$ -glucosidase). There are also marked seasonal changes in biotic and abiotic factors that

affect the biological component of soil resources. Vegetative cover, influenced by seasonal changes, has a strong impact on soil microbiological processes. In degraded soils of arid and semi-arid regions, changes in soil moisture regimes can also affect MBC and activity (Fterich *et al.*, 2014).

The importance of macro-organisms (e.g., earthworms, termites) for restoring soil quality has been widely recognized for centuries. Conversion of PT to CA, with crop residue mulch and cover cropping (Figure 4), can increase earthworm activity and also improve structural properties, but the conversion can also have implications regarding transport of agricultural pollutants into the drainage water. Experiments conducted in central Mexico indicated that conversion of PT to CA improved soil surface aggregation and aggregate stability, increased water infiltration, and enhanced most parameters related to soil quality (Castellanos-Navarrete *et al.*, 2012). Therefore, risks of soil deterioration can be mitigated through adoption of land use and management systems which improve soil biological processes, and introduction of beneficial organisms into soils by selective inoculation. For these and other reasons, the presence of earthworms, termites and other soil biota are often identified as important indicators of quality in tropical soils (Ayuke *et al.*, 2012).

### **Soil recuperative crop production systems**

Farming/cropping systems (rotations, soil fertility management, erosion control, grazing/stocking rate, water management) affect the type, rate and severity of soil deterioration by altering the SOC pool, structural morphology, and other properties. Specifically, crop rotations and grazing can significantly impact SOC pool and the attendant soil properties. Similar to arable

lands, managing quality of rangeland soils is also essential for reducing risks of deterioration. Sustainable management of rangeland soils is especially challenging because of high variability, harsh environments, and the temptation for over-grazing. A reduction in the proportion of palatable perennials, increases in densification (compaction), and declines in SOC are some of the constraints that need to be alleviated. An important strategy to reduce the risks of degrading rangeland soils is to conserve and efficiently manage soil water through an improved understanding of the hydrological attributes. Under West African conditions, construction of stone bunds and establishment of contour vegetative hedgerows can be effective for water conservation (Thapa and Yila, 2012). Establishment and management of forage trees (*i.e.*, *Acacia fadherbia*) and grass-legume mixtures (Muir *et al.*, 2011) can also improve the quality of rangeland soils.

### **Soil resilience**

The term soil resilience refers to the ability of the soil to recover its quality in response to any natural or anthropogenic perturbations. Soil resilience is not the same as soil resistance, because resilience refers to “elastic” attributes that enable a soil to regain its quality upon alleviation of any perturbation or destabilizing influence. Sound rhizospheric processes are essential for soil resilience against anthropogenic/natural perturbations. Being a dominant site of microbial metabolism, it is pertinent to identify management systems that stimulate soil microbiotic activity and related microbial processes. In this context, an “eco-physiological index” has been proposed to assess the impact of soil resilience on soil processes. Managing the quantity and quality of SOC pool is once again a crucial guiding principle in identifying appropriate

management practices that will strengthen resilience and reduce risks for soil deterioration. The SOC pool size is strongly related to the quantity of both above and below-ground biomass-C inputs. It is the assured, continuous input of the biomass-C that moderates MBC, provides a reservoir of plant nutrients (e.g., N, P, S), influences nutrient cycling, and improves/stabilizes soil structural morphology and geometry. The so-called “sustainable land management (SLM)” concept is based on similar strategies of preserving productivity of the resource base for future. There are also some organic management options for reducing soil deterioration risk and improving human health that may have site-specific niches. Biochar, a C-rich soil amendment derived from biomass by pyrolysis, can be produced from human sewage and used to improve soil resilience while also mitigating climate change.

In addition to biotic techniques, ancient farmers also developed mechanical/engineering techniques to sustain and improve their soils. Terraced agriculture evolved independently at several locations around the world (e.g., East Asia, the Himalayan region, Yemen, the Andean region). A study of pre-Columbian terraces from the Paca Valley, Peru, indicated that soil depletion from cultivation has compromised soil quality through loss of fine material and SOC. Overall, however, Paca Valley terraces have improved topsoil retention and supported deep profile with a good soil resilience.

There are no universally applicable techniques of managing soil resilience, but there are several approaches for ensuring sustainable soil management. Each of these approaches has tradeoffs that must be objectively and critically assessed (Figure 6). In view of the heavy demands for agricultural

produce to meet the needs of the growing and increasingly affluent population and emerging economies (e.g., India, China, Brazil, Mexico), the role of agricultural practices and their impact on soil, climate, gaseous emission, water resources, biodiversity, along with economic, political, social and ecologic dimensions must be considered more now than in the past. The ideal strategy is to meet increasing global food demands while simultaneously restoring soil quality, improving the environment, and minimizing the tradeoffs.

In the context of social, economic and cultural issues, it would be a serious omission to ignore poverty, human drudgery and social/gender equity. There is a strong link between poverty and soil quality. When people are poor, desperate and hungry, they pass on their sufferings to the land. Yet, some sociologists have questioned poverty as a major cause of soil/environmental deterioration. Stewardship and desperateness are mutually exclusive. Yield gaps, due to lack of adoption of RMPs in SSA and SA, are poverty traps that require a paradigm shift (Tittonell and Giller, 2013). Since the 1980s, China has bridged the yield gap, alleviated poverty and improved soil quality. Nonetheless, environmental issues remain to be addressed, effectively and immediately, to make China's agricultural revolution a successful venture (Fan *et al.*, 2012).

### **Peak soil vs. endangered soil**

Endangered soil (Tennesen, 2014) and peak soil (losing soil more quickly than it is replaced (Reuters, 2014) are concepts that need to be considered philosophically and scientifically because soil resources are finite and non-renewable over the human time frame. They are also geographically disturbed in a non-uniform manner. Excessive plowing, accelerated erosion, and over fertilization are

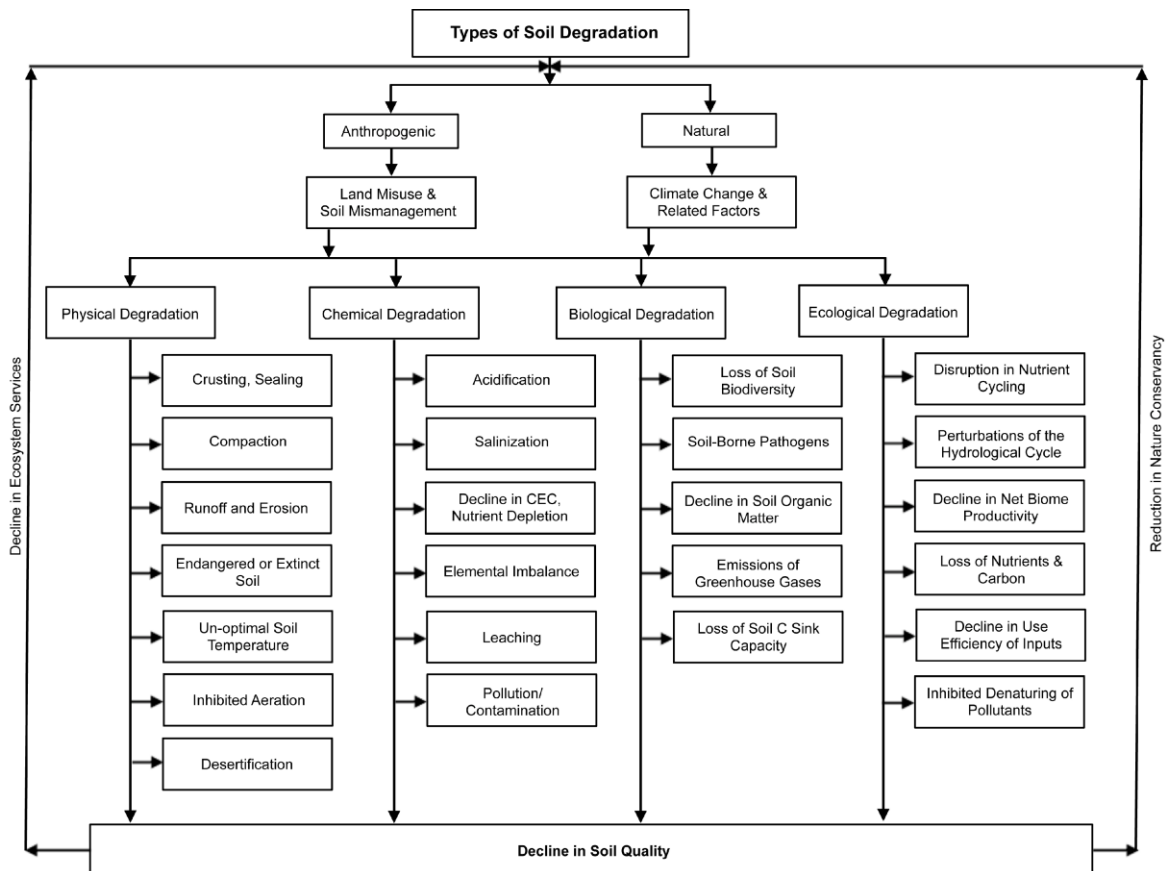

all depleting soil resources, threatening food security, and jeopardizing the environment. Food insecurity is made even more acute by scarcity of soil resources of good quality (prime land) and risks of soil deterioration. Soil degradation is affecting 33% of all soils. Indeed, soil is an essentially forgotten resource (Wall and Six, 2015). In response, a holistic management approach is needed to improve soil quality. Site-specific and appropriate land husbandry practices must be identified to restore physical, chemical, biological, and ecological components of soil quality (Gregory *et al.*, 2012). The goal should be to increase productivity per unit area, time, and energy input; while restoring soil quality and reducing environmental deterioration risks. In terms of soil quality, ecosystem services provisioned by the SOC pool cannot be bypassed by applying commercial chemicals or other technologies. Only by increasing SOC pool can the need for additional inorganic fertilizer N be reduced, especially in degraded soils. Conversion to CA, combined with residue retention and other components, is a sustainable option for several soil-specific conditions (Figure 4). Environmental awareness and stewardship are also important for improving adoption of RMPs and promoting soil restoration.

In conclusion, soil resources are finite in extent, unequally distributed geographically, prone to deterioration by land misuse and mismanagement, but essential to all terrestrial life and human wellbeing. Soil deterioration can be physical (e.g., decline in structure, crusting, compaction, erosion, anaerobiosis, water imbalance), chemical (e.g., acidification, salinization, elemental imbalance comprising of toxicity or deficiency, nutrient deficiency), biological (depletion of SOC pool, reduction in soil biodiversity, decline in microbial biomass-C), or ecological (e.g., disruption in elemental

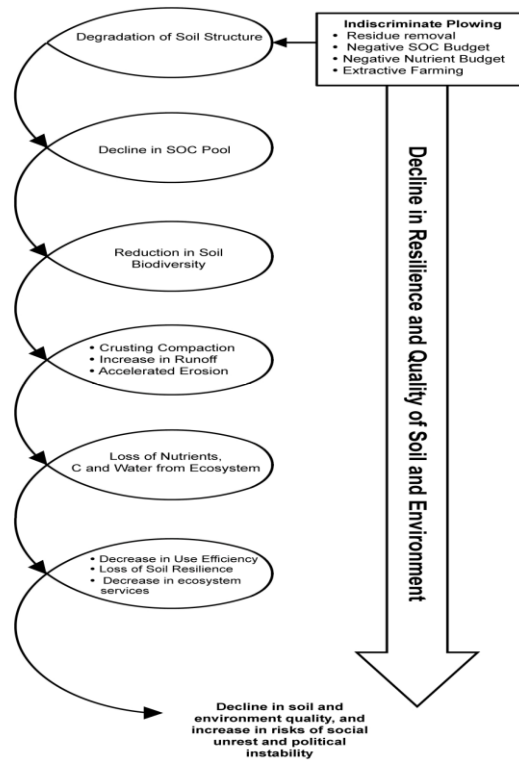

cycling, decline in C sink capacity). Soil deterioration leads to reduction in ecosystem functions and services of interest to human and conservation of nature. The SOC pool, its amount and depth-distribution along with turnover and mean residence time, is a critical component of soil quality and source of numerous ecosystem services. Soil deterioration depletes SOC pool, and its restoration to threshold levels of at least 11 to 15 g kg<sup>-1</sup> (1.1%–1.5% by weight) within the root zone is critical to reducing soil and environmental deterioration risks. Important strategies for soil quality restoration and

reducing environmental deterioration risks are: (i) reducing soil erosion; (ii) creating a positive soil/ecosystem C budget; (iii) improving availability of macro (N, P, S) and micro-nutrients (Zn, Fe, Cu, Mo, Se); (iv) increasing soil biodiversity especially the microbial process; and (v) enhancing rhizospheric processes. The ultimate goal should be to adopt a holistic and integrated approach to soil resource management. The finite nature of soil resources must never be taken for granted they must be used, improved, and restored.
